Preliminary Analysis

Introduction and Data

In the United States, climate change has become a heavily contentious and debated issue. The climate crisis is one of the largest issues that we are facing today, and understanding the general population's stance and views on climate change is important for policy making decisions. There have been a myriad of studies looking at what factors are correlated with a belief in climate change, like Robinson and Furnham's (2022) study: Correlates of belief in climate change: Demographics, ideology and belief systems. There are also studies investigating companies' willingness to pay to reduce climate change, like Zhao et. al (2018): Factors influencing companies' willingness to pay for carbon emissions: Emission trading schemes in China. However, there have not been very many studies examining what impacts individuals willingness to pay to counteract climate change. This is a very important area to examine since public support for climate change action is necessary to influence governments to make changes - like public support for carbon reduction policies which we will examine later.

The question we aim to answer throughout this data analysis is: How do individual beliefs (regarding climate change, political stances, education levels, and views on the role of government) influence personal willingness to spend to reduce climate change?

In this dataset we anticipate that there will be a strong positive correlation between individuals that are more liberal and higher educated and willingness to pay to reduce climate change. We also anticipate the reverse, that individuals that are less educated and more conservative will have lower willingness to pay to support climate change. We also expect that the more an individual believes in the reality of global warming and the more pressing they find the issue to be, the more likely they are to be willing to pay to reduce greenhouse gas emissions.

The data set that we are analyzing comes from The National Surveys on Energy and Environment (NSEE). The NSEE is a biannual national opinion survey. This data set contains 18 survey batches collected from Fall 2008 to Spring 2017. Each case represents an individual's responses to the survey questions. There are 15,136 total cases.

Relevant variables:

CARBONTAX - These are 3 variables that look at different levels of willingness to pay in support of the Carbon tax in this general format: Support for Carbon fuels tax if it raises costs by X\$ a month. What if the carbon fuels taxes significantly lowered greenhouse gases but increased your energy costs by X dollars a month? Would you strongly support, somewhat support, somewhat oppose or strongly oppose this type of system?

STATE_RPS_ECONOMY- This measures the level of agreement respondents have with this statement- State governments will boost their economies by requiring greater use of renewable energy.

INTL_ECONOMICIMPACT- This measures the level of agreement respondents have with this statement- Overall, the U.S. economy would benefit from leaving the international climate treaty designed to reduce greenhouse gas emissions)

DEMOG_POLVIEWS: This reports respondents Political beliefs, on a scale from conservative to liberal

GW_CONCERN: This reports how concerned respondents are about the issue of global warming.

BELIEVER_IMMEDIACY: This reports if respondents believe that global warming requires immediate government action.

GOVT_FED: This measures the level of agreement respondents have with this statement- How much responsibility does the federal government have for taking actions to reduce global warming?

DEMOG_EDU: The Highest level of education respondents have.

Data wrangling

The majority of our data cleaning entailed removing NA values (there were a lot since not all questions were asked each year), as well as Not Sure or Refused to answer (Since they don't provide any real information into how the respondent stands on economic or climate based issues).

In terms of data wrangling - the majority of it came prior to graphing and the creation of models - many variables had string responses which made it harder to read comparisons. We had to convert the variable INTL_ECONOMICIMPACT from String responses to numerical responses in order to take an average value of the responses for the different BELIEVER_IMMEDIACY values. We also simplified WAVE_NUMBER into just the year that the surveys were taken and converted them into Date data types for ease of graphing. January 1st was given as an arbitrary date and does not represent the true date that the surveys were taken. For our model,

we simplified the variable DEMOG_POLVIEWS to only have 3 political standings: We combined Very liberal and Somewhat liberal to just be Liberal, and combined Very Conservative and Somewhat Conservative to just be Conservative, and left Moderate the same. This was necessary in order to allow the decision tree to be readable - and to have enough data at each end node.

We created one important variable that we will use in our analysis: CARBON-TAX_SUPPORT: This variable takes in the 3 levels of willingness to pay for the carbon tax, and returns the maximum value a given individual will be willing to pay for the carbon tax - or if they are unwilling to pay at all.

In our model, we plan to use CARBONTAX_SUPPORT as our outcome variable that will be predicted by our decision tree. This was the variable in our data set that we thought was the best for showing an individual's willingness to pay to reduce climate change, since this tax explicitly attempts to reduce greenhouse gas emissions by increasing the prices of fossil fuels. So, it is our best measure of what individuals care about more, the environment, or their own financial standing. We thought that two of the more important factors that will determine willingness to pay for carbon reduction practices would be if they do or do not believe in global warming in the first place - and their political ideologies, since global warming has increasingly become a political issue. We are using GW_BELIEF (if individuals believe in global warming or not), and DEMOG_POLVIEWS (the respondents political beliefs), to predict what level of the Carbon tax individuals will be willing to pay - we model this using a decision tree.

    fill = "Response"
  ) +
  theme_minimal() +

```

```
theme(axis.text.x = element_text(angle = 35, hjust = 1, size = 5))
```

This graph shows the level of support respondents have for the different variations of the Carbon tax which are designed to significantly lower greenhouse gases. Revenue Neutral means that every dollar collected by the government would be returned to the public as an income tax rebate. 15\$/month means it would increase energy costs by 15 dollars a month, and 50\$/month means it would increase energy costs by 50\$/month. These charts show that the more concerned an individual is about global warming, the more they will support the various levels of carbon tax - and the support decreases as costs go up. The largest support for carbon tax is found in individuals who are very concerned about global warming at the revenue neutral level - and there is almost no support found for individuals who are not concerned about global warming at all at any level of cost.

```
#Graph 4: Economic Impact Perception vs. Belief in Climate Immediacy
#Removing NA values for graph

    x = "Political Views",
    y = "Federal Gov Level Responsibility",
    fill = "% Support for Carbon Tax",
    title = "Support for Carbon Tax by Gov Responsibility & Political Views"
  ) +
  theme_minimal()

```

This graph shows the percent of individuals that support the carbon tax by their political ideology, and how much responsibility they believe the Federal Government has for taking action to reduce global warming. This shows that across political ideologies- the more an individual believes it is the responsibility of the government to reduce global warming, the more likely they are to be willing to pay for the carbon tax. Additionally- overall the more liberal an individual is the more likely they are to be willing to pay for the carbon tax.

Discussion

Analysis of Results

Our data supports our claim that more liberal minded individuals who believe in climate change are more likely to be willing to personally pay to attempt to limit the effects. Among those that are willing to pay, however, the group that was willing to pay the most on average were conservatives who did not believe in climate change. This result is very surprising, however we believe that it may be due to a small sample size, as described in the next section. For our decision tree regarding if individuals are willing or not to pay extra taxes, we got an AUC score of 0.73. This is not particularly good and we could probably do better if we fit a forest rather than just one decision tree. Similarly, with our decision tree regarding how much people would be willing to put towards taxes for climate change, our confusion matrix shows that our fitting did an extremely poor job for the three different classes. This could also probably be remedied by fitting a forest rather than a single tree. Going forward, we will make sure to fit forests rather than trees, and even though trees are visually very good and representing the splits we wanted, we many test some other models aswell.

Reliability and Validity

The most major problem that we faced in our data analysis was that while our survey data spanned years from 2008 - 2017, there were some questions that - while very applicable to our data- were not asked in every year. This resulted in numerous NA values throughout the project, which reduced our sample size from 15,136 to a low of 766 in the graph Economic Impact Perception vs. Belief in Climate Immediacy - which used INTL_ECONOMICIMPACT - since this question was only asked in 2017. In the best case scenario, this means that the results shown in this graph can measure the Economic Impact Perception vs. Belief in Climate Immediacy in 2017 exclusively, but realistically the results cannot be extended beyond that year - especially given the political climate in 2017, marked by President Trump's decision to withdraw from the Paris Climate Agreement. Public opinion was likely shaped in ways that are not representative of other periods. Thus, while the analysis offers insights into a specific moment in time, it does not provide a stable basis for predicting future trends or drawing broader inferences.

Additionally within our decision tree model, we only had 2,841 rows of observations - since we had to eliminate any rows that had NA values for GW_BELIEF, DEMOG_POLVIEWS, or CARBONTAX_SUPPORT in order for the function to run properly. While the eliminations were done without bias, it still is only 18.76% of the original dataset, and the reduced sample may not reflect the full diversity of public opinion contained in the broader survey data. This limitation directly affects the validity of our model: it is likely overfitted to the available data and may not generalize as well to new or unseen data.

Ethical Concerns

One potential ethical concern in our project could arise from the simplification of political ideology categories. To create a more readable dataset, we grouped "very liberal" and "somewhat liberal" respondents into a single "liberal" category, and did the same for "very conservative" and "somewhat conservative" respondents, combining them into "conservative." While this made the analysis more clear, it also risks obscuring differences in political attitudes. As a result, our findings could produce misleading conclusions regarding certain groups' behaviors or actions. Another concern comes to be when looking at our primary outcome variable: respondents' willingness to pay for a carbon tax. While we were trying to observe a connection between global warming, political ideologies, and their willingness to pay to better the environment, what is not included in our analysis is that an individual's unwillingness to pay may not be related to how much they care about the environment, but could just be for financial reasons. Financial constraints could easily influence responses, particularly for higher proposed amounts (e.g., \$10, \$15, or \$50 per month). Another ethical risk of our project would arise if the results were to be used in a policy-making or public communication context. For example, oversimplified interpretations could reinforce political stereotypes—such as suggesting that "Republicans don't care about the environment." Such conclusions would misrepresent

the data, and could deepen existing political divisions. To try to avoid this, we tried to present our findings descriptively, without making normative claims.
